# Eye-tracking methodology for the assessment of social function in infancy

Karri Gillespie-Smith, James Boardman, Ian Murray, Jane Norman, Anne O'Hare & Sue Fletcher-Watson  
University of Edinburgh, UK

## Introduction

- There is a need for better understanding of cognitive development in the first year as a prerequisite for early identification of deviance from typical developmental trajectories, particularly in children with known vulnerabilities.
- Existing studies of early social cognition have not taken into account factors known to affect adult social attention such as stimulus complexity (1).
- We used eye-tracking methodology to assess social functioning in infants who are typically developing. The hypotheses were; i) Attention to social information in infancy differs across stimuli of increasing social complexity; ii) Attention to social information across tasks can be quantified by social preference scores; iii) Social preference score is related to infant age at time of assessment.

## Method

- 30 typically developing infants (15 female; 15 male) ; age range = 6.2 – 12.9 months (mean = 8.3 months) were tested following ethical approval by University of Edinburgh.
- A battery of visual tasks were presented on a Tobii x60 eye-tracker. The tasks were shown in three trial blocks which lasted 6 minutes, combining both novel visual tasks with previously tested tasks provided by British Autism Study of Infant Siblings (BASIS)<sup>a</sup>.
- Analysis: Social preference scores = the percentage of mean time looking at the social area of a scene versus mean total looking time for that scene.

**Figure 1** : An infant being eye-tracked.

## Results

- Face-scanning:** Infants fixated on the eyes longer than the mouth (means = 1.82s versus 0.29s;  $p < .001$ ) and looked at eyes quicker than the mouth (means = 2.32s versus 3.90s;  $p = .02$ ; Figure 2A-C).
- Face Pop-out:** Each area of interest, bird, car, face noise, phone was fixated less than the face (means = 0.36s, 0.45s, 0.43s, 0.22s versus 1.78s; all  $ps < .001$ ; see Figure 2D-F). Time to first fixation was slower to the other areas bird, car, phone compared to the face (means = 4.20s, 3.66s, 4.27s versus 2.44s; all  $ps < .001$ ), except time taken to fixate the face compared to face-noise (means = 2.44s versus 3.10s;  $p = .061$ ).
- Social Preferential Looking:** There was no difference in fixation duration to social scenes compared to non-social scenes (means = 1.68s versus 1.40s;  $p = .09$ ; see Figure 2G-I). Time to first fixate was quicker for social scenes compared to non-social scenes (means = 1.19s versus 1.54s;  $p = .009$ ).
- Social Preference variables:** Social preference scores were all significantly correlated with each other for all three tasks (face-scanning with pop-out:  $r = .638$ ,  $p < .001$ ; face scanning with social PL:  $r = .546$ ,  $p = .002$ ; pop-out with social PL:  $r = .497$ ,  $p = .005$ ).
- Relationship between social cognition, and infant age:** A single social composite score was created by averaging social preference scores across the three eye-tracking tasks. Social preference score did not correlate with infant age at testing.

## Discussion

- The preference that infants show for social content in eye-tracking tasks is moderated by complexity of the display.
- Social cognition in infancy can be summarised by a composite score, derived from gaze behaviour which varies across tasks.
- The composite score may have greater utility than single tasks when developing early markers of later social cognitive impairment.
